After reading this article, the reader should be able to:

1. Discuss the science behind Platelet Rich Fibrin.
2. Discuss how Platelet Rich Fibrin is prepared.
3. Discuss how Platelet Rich Fibrin might enhance surgical healing.

INTRODUCTION

Reconstructive dental surgeons are constantly looking for an “edge” that jump starts the healing process to maximize predictability as well as the volume of regenerated bone. Is it bone morphogenetic protein-2 (BMP-2), recombinant platelet derived growth factor-BB (rhPDGF-BB), platelet rich plasma (PRP), plasma rich in growth factors (PRGF), or a combination of all four? Let me say from the outset, “I don’t know” and this report will not provide the answer, but it will serve to introduce a second generation platelet concentrate, platelet-rich fibrin (PRF). PRF is easy to obtain, less costly, and a possibly very beneficial ingredient to add to the “regenerative mix.”

Pre-implant reconstruction of the deficient alveolar ridge facilitates ideal prosthetic positioning of implants and improves the long-term success of implant-supported restorations. Regardless of the choice of graft material (autograft, allograft, xenograft or alloplast) or membrane selection (bioresorbable or nonresorbable), predictable bone regeneration is dependent upon 4 major biologic principles: primary wound closure, blood supply, space maintenance, and wound stability. Bone grafting is most successful when it occurs in a contained, well-vascularized environment, stressing the importance of primary closure and the promotion of angiogenesis.

Blood supply provides the necessary cells, growth factors, and inhibitors to initiate the osteogenic biomineralization cascade. Injury to blood vessels during oral surgical procedures causes blood extravasation, subsequent platelet aggregation, and fibrin clot formation. The major role of fibrin in wound repair is hemostasis, but fibrin also provides a matrix for the migration of fibroblasts and endothelial cells that are involved in angiogenesis and responsible for remodeling of new tissue. Platelet activation in response to tissue damage and vascular exposure results in the formation of a platelet plug and blood clot as well as the secretion of biologically active proteins. Platelet alpha (α) granules form an intracellular storage pool of growth factors (GF) including platelet-derived growth factor (PDGF), transforming growth factor β (TGF-β, including β-1 and β-2-isomers), vascular endothelial growth factor (VEGF), and epidermal growth factor (EGF). Insulin-like growth factor-1 (IGF-1), which is present in plasma, can exert chemotactic effects towards human osteoblasts. After platelet activation, α granules fuse with the platelet cell membrane transforming some of the secretory proteins to a bioactive state. Active proteins are secreted and bind to transmembrane receptors of target cells to activate intracellular signaling proteins. This results in the expression of a gene sequence that directs cellular proliferation, collagen synthesis, and osteoid production.

Platelet Rich Plasma

Several studies have shown that bone regenerative procedures may be enhanced by the addition of specific growth factors. Platelet-rich plasma (PRP) was proposed as a method of...
introducing concentrated growth factors PDGF, TGF-β, and IGF-1 to the surgical site, enriching the natural blood clot in order to expedite wound healing and stimulate bone regeneration. A natural human blood clot contains 95% red blood cells (RBCs), 5% platelets, less than 1% white blood cells (WBCs), and numerous amounts of fibrin strands. A PRP blood clot, on the other hand, contains 4% RBCs, 95% platelets, and 1% WBCs. The classic PRP production protocol requires blood collection with anticoagulant, 2 steps of centrifugation, and artificial polymerization of the platelet concentrate using calcium chloride and bovine thrombin. Since its introduction, PRP has been used in conjunction with different grafting materials in bone augmentation procedures. To date, the results from these studies are controversial and no conclusions can be drawn regarding the bone regenerative effect of PRP.
Platelet Rich Fibrin

Platelet-rich fibrin (PRF) represents a new step in the platelet gel therapeutic concept with simplified processing minus artificial biochemical modification. Unlike other platelet concentrates, this technique requires neither anticoagulants nor bovine thrombin (nor any other gelifying agent), making it no more than centrifuged natural blood without additives. Developed in France by Chouroukroun et al in 2001, the PRF production protocol attempts to accumulate platelets and released cytokines in a fibrin clot. Though platelets and leukocyte cytokines play an important part in the biology of this biomaterial, the fibrin matrix supporting them certainly constitutes the determining element responsible for the real therapeutic potential of PRF. Cytokines are quickly used and destroyed in a healing wound. The synergy between cytokines and their supporting fibrin matrix has much more importance than any other parameter. A physiologic fibrin matrix (such as PRF) will have very different effects than a fibrin glue enriched with cytokines (such as PRP), which will have a massively uncontrollable and short-term effect.

Preparation and Clinical Applications of PRF

PRF preparation requires an adequate table centrifuge (figure 1), (PC-02, Process Ltd., Nice, France), and collection kit including: a 24 gauge butterfly needle and 9 ml blood collection tubes (figure 2). The protocol for PRF preparation is very simple: whole blood is drawn into the tubes without anticoagulant and is immediately centrifuged. In a few minutes, the absence of anticoagulant allows activation of the majority of platelets contained in the sample to trigger a coagulation cascade. Fibrinogen is at first concentrated in the upper part of the tube, until the effect of the circulating thrombin transforms it into a fibrin network. The result is a fibrin clot containing the platelets located in the
middle of the tube, just between the red blood cell layer at the bottom and acellular plasma at the top (figure 3). Unlike PRP, the PRF results from a natural and progressive polymerization which occurs during centrifugation. This clot is removed from the tube and the attached red blood cells scraped off and discarded (figures 4,5). The PRF clot (figure 6) is then placed on the grid in the PRF Box® (figure 7) (Process Ltd., Nice, France), and covered with the compressor and lid. This produces an inexpensive autologous fibrin membrane in approximately one minute (figure 8). The PRF Box® was devised to produce membranes of constant thickness that remain hydrated for several hours and to recover the serum exudate expressed from the fibrin clots which is rich in the proteins vitronectin and fibronectin. The exudate collected at the bottom of the box may be used to hydrate graft materials, rinse the surgical site, and store autologous grafts.

Concerning specific procedures, PRF membranes may be utilized in combination with graft materials to expedite healing in lateral sinus floor elevation. Choukroun et al. evaluated the potential of PRF in combination with freeze-dried bone allograft (FDBA) to enhance bone regeneration in lateral sinus floor elevation. Nine sinus floor augmentations were performed with 6 sinuses receiving PRF + FDBA particles (test group) and 3 sinuses receiving FDBA without PRF (control group). Four months after implantation (test group) and 8 months later (control), bone specimens were
harvested with a 3mm diameter trephine during implant insertion. Histologic evaluations revealed the presence of residual bone particles surrounded by newly formed bone and connective tissue. At 4 months, the histologic maturation of the test group appeared identical to that of the control group after a period of 8 months with the quantities of newly formed bone equivalent between the two protocols. The use of PRF in combination with FDBA to perform sinus floor augmentation seemed to accelerate bone regeneration.

When performing ridge augmentation, PRF membranes are used to protect and stabilize the graft materials (figures 9-11). The membranes act as fibrin bandages, accelerating the healing of the soft tissues, facilitating the rapid closure of the incision despite a substantial volume of added bone (figures 12-14). In a two-part publication, Simonpieri et al. reported on a new technique for maxillary reconstruction using FDBA, PRF membranes and 0.5% metronidazole solution. A small quantity of a 0.5% metronidazole solution (10 mg) was used to provide an efficient protection of the bone graft against unavoidable bacterial contamination. PRF membranes were used to protect the surgical site and foster soft tissue healing and PRF fragments were mixed with the graft.

particles. The membranes may be cut into few-millimeter fragments and mixed with the graft material (figures 15,16), functioning as a “biological connector” between the different elements of the graft, and as a matrix which favors neo-angiogenesis, the capture of stem cells, and the migration of osteoprogenitor cells to the center of the graft.\textsuperscript{5,6} Using the reported protocol, they consistently observed a high degree of gingival maturation after healing with a thickening of keratinized gingival tissues that improved the esthetic integration and final result of their prosthetic rehabilitations. In addition, all their clinical experiences emphasized that the use of PRF seemed to reduce postoperative pain and edema, and limited even minor infectious phenomena.\textsuperscript{31}

To get thick small discs or “plugs” of PRF, useful in protecting extraction sites, the PRF clot is placed into the cylinder in the PRF Box\textsuperscript{®} and slowly compressed with the piston (figures 17-19). The small discs measure 1 cm in diameter and are easily inserted into residual extraction defects to expedite soft tissue healing in site preservation procedures permitting ideal prosthetic implant placement (figure 20). PRF plugs are also positioned in the implant osteotomy to facilitate sinus floor elevation using a crestal core elevation (CCE) procedure\textsuperscript{33} or osteotome-mediated sinus floor elevation (OMSFE) with simultaneous implant placement.\textsuperscript{34} Diss et al\textsuperscript{35} documented radiographic changes in the apical bone levels on 20 patients with 35 microthreaded implants placed using OMSFE with PRF as the sole grafting material. Despite a limited residual subantral bone height (RSBH) of 4.5 to 8 mm, a healing period of 2-3 months
was found to be sufficient to resist a torque of 25 Ncm applied during abutment tightening. One implant failed during the initial healing, but at one year, 34/35 implants were clinically stable and the definitive prostheses were in function, resulting in a survival rate of 97.1%. The mean endosinus bone gain was 3.2 mm with radiographic documentation of apical displacement of the sinus floor. Not only can PRF be used in lieu of particulate grafting to predictably elevate the sinus floor using a crestal approach, but the PRF membrane can provide protection for the sinus membrane during the use of an osteotome, and in case of perforation, the fibrin matrix can aid in wound closure.35,36 The authors always utilize PRF membranes in the lateral window osteotomy procedure to line the

membrane prior to grafting as “membrane insurance” possibly sealing an undetected perforation which can lead to serious postoperative sequelae.

**DISCUSSION**

PRF is a matrix of autologous fibrin, in which are embedded a large quantity of platelet and leukocyte cytokines during centrifugation.\(^{24,25}\) The intrinsic incorporation of cytokines within the fibrin mesh allows for their progressive release over time (7-11 days), as the network of fibrin disintegrates.\(^{30}\) The easily applied PRF membrane acts much like a fibrin bandage,\(^{5}\) serving as a matrix to accelerate the healing of wound edges.\(^{11}\) It also provides a significant postoperative protection of the surgical site and seems to accelerate the
integration and remodeling of the grafted biomaterial.\textsuperscript{26-27} According to Simonpieri et al,\textsuperscript{31} the use of this platelet and immune concentrate during bone grafting offers the following 4 advantages: First, the fibrin clot plays an important mechanical role, with the PRF membrane maintaining and protecting the grafted biomaterials and PRF fragments serving as biological connectors between bone particles. Second, the integration of this fibrin network into the regenerative site facilitates cellular migration, particularly for endothelial cells necessary for the neo-angiogenesis,\textsuperscript{24} vascularization and survival of the graft. Third, the platelet cytokines (PDGF, TGF-β, IGF-1) are gradually released as the fibrin matrix is resorbed, thus creating a perpetual process of healing.\textsuperscript{20,30} Lastly, the presence of leukocytes and cytokines in the fibrin network can play a significant role in the self-regulation of inflammatory and infectious phenomena within the grafted material.\textsuperscript{21}

**CONCLUSION**

Early publications and clinical experience seem to indicate that PRF improves early wound closure, maturation of bone grafts, and the final esthetic result of the peri-implant and periodontal soft tissues. Additional reports are forthcoming, highlighting the many clinical applications and healing benefits of this second generation platelet concentrate.

## Continuing Education JIACD Quiz #2

1. Predictable bone regeneration is dependent upon which major biologic principles?
   a. Primary wound closure
   b. Blood supply
   c. Space maintenance and wound stability
   d. All of the above

2. The major role of fibrin in wound repair is hemostasis.
   a. True
   b. False

3. Platelet activation in response to tissue damage and vascular exposure results in the formation of a platelet plug and blood clot as well as the secretion of biologically active proteins.
   a. True
   b. False

4. Platelet alpha (α) granules form an intracellular storage pool of growth factors which include all the following except?
   a. Platelet-derived growth factor
   b. Bone morphogenetic protein
   c. Vascular endothelial growth factor
   d. Epidermal growth factor

5. The PRF technique requires anticoagulants in order to process it.
   a. True
   b. False

6. PRF preparation requires which of the following?
   a. Adequate table centrifuge
   b. 24 gauge butterfly needle
   c. 9 ml blood collection tubes
   d. All of the above

7. The protocol for PRF preparation requires immediate centrifugation after blood collection.
   a. True
   b. False

8. The PRF Box® was devised to produce:
   a. Membranes of constant thickness
   b. Recovery of serum exudate
   c. All of the above
   d. None of the above

9. PRF membrane acts like a fibrin bandage, serving as a matrix to accelerate healing of soft tissues.
   a. True
   b. False

10. PRF is a matrix of autologous fibrin, in which are embedded a large quantity of platelet and leukocyte cytokines during centrifugation.
    a. True
    b. False
